Abstract

A BCS-based biowaiver for generic drugs requires high drug solubility throughout the physiological pH range plus identical product quality and near-identical reference product content to meet recommendation standards outlined by the 2017 FDA Guidance. The International Council for Harmonization gave its authorization to these procedures during 2018. The FDA employs identical terms while discussing BCS-based biowaiver approvals for BCS class III medications (highly soluble but partially permeable substances). The development of IVIVC using traditional mass balance deconvolution methods becomes improbable for BCS III medicines when extremely rapid dissolution occurs. Physiologically based pharmacokinetic models separate different processes which shape the given function by analyzing dissolution and gastrointestinal transit and permeation. IVIVC development through various compartmental absorption and transit model modifications enables drug companies to obtain biowavers for BCS III medications. Some questions about this topic continue to remain unanswered. A systematic assessment of PBPK model development for IVIVC and biowaiver applications leads to identifying essential challenges and gaps in this area through this review. The paper advocates for further research on excipient dissolution alongside penetration effects alongside development of virtual clinical study simulations that unite in vitro data with in vivo bioequivalence confirmation.

Keywords: Generic Medications, Bioequivalence, Biowaiver, BCS Classification

Introduction

Pharmacological substances receive classification through the BCS framework based on their intestinal permeability combined with their water solubility characteristics [1]. Intestinal permeability, dissolution rate, and solubility represent the three decisive elements which shape how rapidly and in what amount IR solid oral-dosage forms absorb medication through oral routes according to the BCS system. The criteria link to measured in vitro dissolution properties of drug products. The Biopharmaceutics Classification System (BCS) functions as a beneficial instrument for pharmaceutical development while also providing regulations for in vivo bioequivalence research exemptions. BCS provides a scientific explanation for describing the three key rate-limiting factors that affect oral absorption through its detailed descriptions.

- (1) Drug release from the dose mechanisms
- (2) The drug exists in dissolved form throughout the entire gastrointestinal fluid system [2].
- (3) Drug compounds accessing the hepatic circulation through the GI membrane [3].

BCS class definitions start with the maximum strength found in IR products to determine drug solubility. A drug substance meets the highly soluble classification standard when its highest possible dosage strength completely dissolves in 250 milliliters or below of aqueous solution with a pH rating between 1.0 and 7.5. Otherwise, the classification is poor. The standard bioequivalence research approach that tests drugs on fasting volunteers using glass water amounts to 8 ounces gives rise to the 250 mL

volume estimate. The permeability classification of medication substances is determined through measurements of human intestinal absorption rates or it derives from direct intestinal membrane permeability data [4].

Through USP Apparatus I at 100 rpm or USP Apparatus II at 50 rpm in solutions no larger than 900 milliliter, the product quality control evaluates the drug ingredient for its dissolving time. Based on the medications' solubility and permeability in the GIT mucosa, the BCS divides them into four basic classes. These distinct divisions are found in each class of the biopharmaceutical categorization system.

Class I: It is classification represents medications with strong permeability and solubility properties leading to maximum absorption in the body.

Class II: Medications having low solubility and strong permeability, absorb into body at a rate which depends on how fast they dissolve.

Class III: Low permeability, high solubility, and permeability-limited absorption

Class IV: Very low oral bioavailability because of low solubility and restricted permeability [5].

The Objectives:

- In vivo pharmaceutical efficiency evaluation relies on in vitro measurement data regarding permeability and solubility.
- It is necessary to identify a class of oral immediate-release solid forms of medication since in vitro dissolving studies can verify their bioequivalence.
- The paper presents systems which help classify pharmaceutical substances through analysis of their permeability characteristics combined with their solubility properties along with their dosage form dissolution properties [6].
- The author proposes criteria to enable scientists to recognize disposable clinical bioequivalence tests that would maximize drug development and review process success.
- The research presents classification methods which combine permeability and solubility characteristics of products with dosage form dissolution abilities [7].

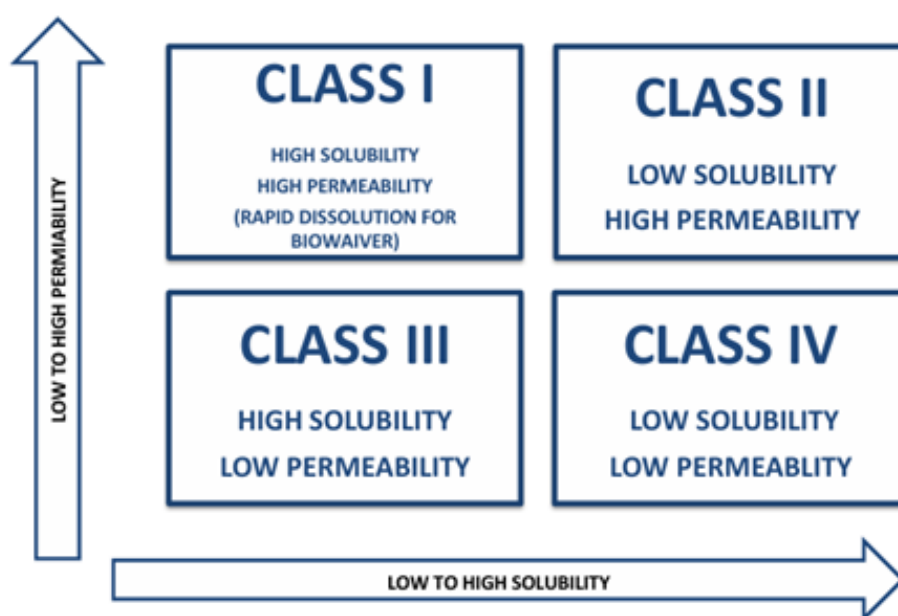

Figure 1: The Illustration of BCS classification

Class I

The drug exhibit rapid absorption as well as dissolution inside the body similar to how oral dose work. Because Class I medicines rapidly absorb and dissolve within the body the measurements of bioequivalence together with bioavailability become irrelevant for these medications. The medications qualify as suitable controlled drug administration options when they demonstrate pharmacokinetic and pharmacodynamic suitability for the point. The drug molecules that release in these situations can be made of diverse substances such as constant surface area drug delivery shuttles, single composition osmotic tablet systems, microspheres, and multiporous oral drug absorption systems. The drug delivery approaches include matrix diffusion control systems and dual release drug absorption systems as well as granulated hydrogel systems and

delayed pulsatile hydrogels together with stomach protective for absorption of drug and technology for Drug Delivery using pelletized pulsatile delivery systems and microparticles, as well as bioerodible improved medication absorption systems that are spheroidal, configurable, and comprise hydrogels for solubility control and the stabilizing mechanism of pellet delivery systems.

Class II

Drug dissolution rate determines bioavailability at this classification because molecules exhibit high permeability yet poor solubility. The pharmaceutical compounds display different bioavailability parameters which need multiple dissolving enhancement methods to boost their available quantities within the body. The medication design can incorporate controlled release functionality in products from this category. The list of

pharmaceutical techniques includes solid dispersion methods together with emulsion or microemulsion systems and surfactants and lyophilized fast-melt systems and classical micronization and complexing agents such as cyclodextrins. Nanosized carriers such as nanoemulsion, nanosuspension, nanocrystals and Zer-Os tablet technology and Trigras, Soft Gel as well as the osmotic system have proven best in enhancing water-insoluble compounds' bioavailability by improving their solubility levels.

Class III

It is class of pharmacological substance requires intestinal membrane penetration to determine their absorption speed as their rate-limiting step. The bioavailability rate controls medication release from dosage forms because absorption limits based on how quickly permeation occurs. The ranitidine drugs with differ-

ent dissolution properties produce the same plasma concentration-time profile when administered in vivo. The pharmaceutical ingredients possess low absorption potential so permeability enhancement becomes essential. Producing medications with controlled release features remains difficult for industries today.

Class IV

In this class, the drugs exhibit weak bioavailability together with variable responses. Intestinal permeability, stomach emptying, and drug dissolving rate are some of the variables that affect basic bioavailability. Oral administration is generally inappropriate for these medications but nano-suspensions and other drug delivery systems represent suitable options when medication use by mouth becomes necessary [8].

BCS Classification of Drug with Examples

High Solubility	Low Solubility
CLASS 1	CLASS 2
Captopril	Itraconazole
Enalapril	Verapamil
Diltiazem	Piroxicam
Labetolol	Diclofenac
Phenylalanine	Phenytoin
Antipyrin	Carbamazepine
Metoprolol	Flurbiprofen
Propranolol	Ketoprofen
CLASS 3	CLASS 4
Verapamil	Terfenadine
Naproxen	Furosemide
Itraconazole	Cyclosporine
Piroxicam	Chlorothiazide
Flurbiprofen	Neomycin
Ketoprofen	Ritonavir
Carbamazepine	Ellagic acid
Phenytoin	Colistin
Diclofenac	Chlorthalidone

Main Purpose of BCS

Boundaries of BCS Class

The BCS classification can be determined through the border properties of solubility and permeability and dissolution.

- **Solubility:** When a drug dissolves fully in 250 milliliters of water with a pH between 1 and 7.5 at 37 degrees Celsius, it is said to be very soluble.
- **Permeability:** A pharmacological substance demonstrates high permeability when its absorption reaches or exceeds 90% of dose intake based on mass-balance methods or intravenous reference dosage comparison.
- **Dissolution:** It takes place when drug substance ingredients reach 85% dissolution rate within 30-minute USP Apparatus 1 or 2 testing using 900 mL or less buffer solutions thus establishing the drug product as quickly dissolving [9].

An Essential Term Under BCS

Bioavailability: Bioavailability represents the speed along with degree to which medications and their active elements enter bloodstream for delivery to the place of action.

Bioequivalence: The same doses of two medication products become bioequivalent when their bioavailability exhibits similar absorption characteristics under similar testing environments [10].

Biopharmaceutics Drug Disposition Classification System (BDDCS): The system described by Wu and Benet functions as an analytical tool that predicts the characteristics of drug disposition. The assessment system evaluation relies on data about

solubility behavior alongside the rate of membrane permeation and the quantity of metabolic breakdown. This document reviews published BDDCS collection papers while assigning BDDCS classes to recently approved medications. Within its content the document presents documented sources used for parameter statements and it adjusts several previously recorded classification groups. This work examines how BDDCS classification benefits drug development projects before human or animal dosing of new molecular entities and reviews BCS class assignments versus BDDCS classifications when both systems exist. Furthermore it modifies the proposed solubility standards for prehuman-dose drug classification [11].

Solubility: The GI tract absorption of new chemical entities remains restricted due to their low solubility rates which range between 40–70% of total compounds identified today [12]. Research has identified key molecular features which determine poor aqueous hydration along with examination of strong crystal lattices preventing solubility. Compounds with stretched and rigid shapes that typically appear flat will remain soluble only when existing in the solid phase. These structural characteristics allow molecules to form tight crystals by engaging in H bonds, π - π stacking interactions as well as Van der Waals contacts resulting the strong intermolecular binding. The solvation-limited molecules, in contrast, are lipophilic, pliable, and bigger [13]. Furthermore, certain intermediate compounds have a weak solvation and a strong crystal lattice. These molecules usually have a strong hydrogen bonding ability inside the crystal lattice and are tiny, stiff, and extremely lipophilic. Therefore, medicinal chemists can use the underlying molecular cause of low solubility to guide their techniques for improving water solubility [14].

Permeability

Absorption data obtained during human pharmacokinetic investigations using absolute efficiency and equilibrium balance techniques should be the preferable approach for assessing permeability. High permeability between the medication molecules and absorption vessels is indicated by a bioavailability rate of at least 85%. If the total percentage recovery of the parent medication plus Phase 1 oxidative metabolites and Phase 2 conjugative metabolites in urine surpasses 85% of the dosage that was delivered, high permeability may be deduced. Oxidative and conjugative metabolites serve as the entire basis for metabolite evaluation in feces. A scientific demonstration pointing to metabolite formation occurring after gastrointestinal absorption requires confirmation in order for reduction or hydrolysis metabolites to be excluded. The quantity of parent drug present in feces that stemmed from intestinal secretion or biliary excretion or resulted from unstable metabolite breakdown by microbial action should not be included in the absorption assessment. A pharmacological substance requires proof of high permeability to avoid BCS classification for low permeability [15].

Dissolution

It is the procedure in which a solid medicinal ingredient, such as that found in a tablet or capsule, decomposes and dissolves in a solvent, such as the fluids of your intestines or stomach, to create a solution. A drug's efficacy is ultimately determined by how quickly and how much of it is absorbed into the bloodstream, which is directly impacted by its rate and degree of breakdown. It is the process by which a solute dissolve into a solvent to form a solution combination. Using USP equipment 1 at 100 rpm or apparatus 2 at 50 rpm in 900 mL of buffer solutions (0.1 N HCl/pH 4.5 buffer/pH 6.8 buffer without enzymes), when 85% of the indicated amount of drug ingredient dissolved in 30 minutes, the drug product indicates to have rapid dissolution [16].

indicated amount of drug ingredient dissolved in 30 minutes, the drug product indicates to have rapid dissolution [16].

In vitro Dissolution Testing: One popular technique for forecasting a medicinal product's in vivo (in the body) dissolve behaviour of drug product.

Studies on Bioequivalence: To ascertain whether several formulations of the same medication dissolve and absorb similarly, dissolution profiles are utilized [17].

Comparable in vitro dissolving properties (f2 comparison) in each of the specified circumstances. Test product from a minimum 100,000 units, or 1/10 of the production size [18].

A Drug Product's Eligibility for A Biowaiver Based on BCS

When a single therapeutic dose fails to meet high solubility thresholds but the reference product meets or surpasses such standards under pertinent testing parameters, pharmacokinetic analyses of AUC and Cmax at different doses that include the highest therapeutic quantity offer evidence in favor of BCS-based waivers. Drug products that are absorbed sublingually or buccally do not have a BCS-based biowaiver application. Furthermore, the application of the BCS-based biowaiver technique is limited to situations in which the administration route involves water. If it is also expected that the product will be administered without water, a bioequivalence study should be conducted in which the product is dosed without water (for example, orodispersible products). To be qualified for a BCS-based biowaiver, a medicinal product must fulfill specifications for its excipients and in vitro dissolving ability. The BCS-based biowaiver criteria apply to drug products that depends upon specific conditions including being immediate-release oral systemic dosage forms, having equivalent formulations and strengths as the reference product and meeting solubility and permeability requirements of BCS Class I and III [19].

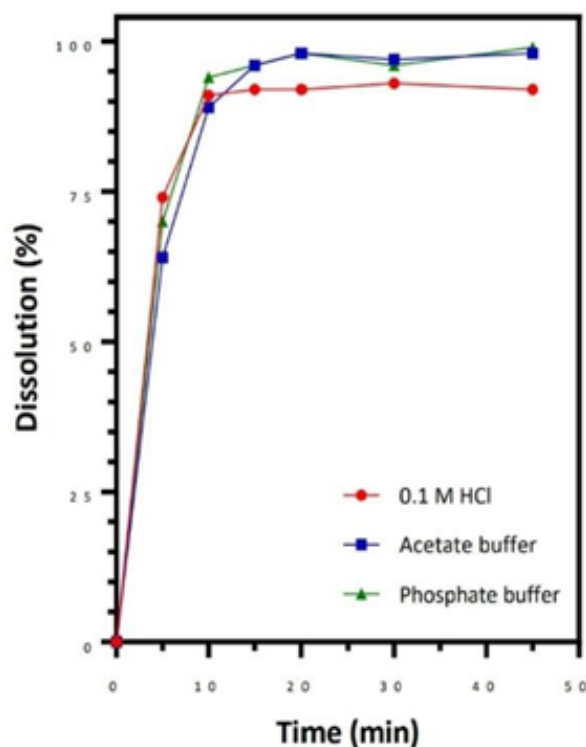

Figure 2: Dissolution (%) and Time(min) graph

Application of Biopharmaceutics

- Therapeutic formulation and design, as well as the assessment of novel therapeutic candidates, are significantly influenced by biopharmaceutics. For example, many medications have problems with stability or solubility, which might hinder proper absorption. To enhance absorption, biopharmaceutical researchers respond by using methods including pH adjustment, particle size reduction, and the creation of prodrugs— inactive substances that the body changes into active medications.

- Biopharmaceutics helps the generic medicine industry develop cost-effective substitutes for name-brand drugs without sacrificing efficacy or quality. The strict bioequivalence testing criteria in this industry are crucial to helping patients all across the world receive safe, easily available drugs.

- The European Medicines Agency (EMA) and U.S. Food and medication Administration (FDA) use biopharmaceutic data for assessing new medication applications. Biopharmaceutic evaluations confirm medication safety and performance requirements before granting availability to the general public. These rules also mandate testing of medication stability alongside solubility and dissolution rates because both influence how a drug functions in the body

- Primary focus of biopharmaceutic research is always patient safety. Researchers can customize therapies to reduce side effects by knowing how different patient populations react to different medications. For example, formulations that take into consideration genetic variations in drug metabolism might be developed using personalized medicine techniques, resulting in safer and more efficient treatments [20].

BCS Exclusion

indicated amount of drug ingredient dissolved in 30 minutes, the drug product indicates to have rapid dissolution [16].

In vitro Dissolution Testing: One popular technique for forecasting a medicinal product's in vivo (in the body) dissolve behaviour of drug product.

Studies on Bioequivalence: To ascertain whether several formulations of the same medication dissolve and absorb similarly, dissolution profiles are utilized [17].

Comparable in vitro dissolving properties (f2 comparison) in each of the specified circumstances. Test product from a minimum 100,000 units, or 1/10 of the production size [18].

Drugs with a Limited Therapeutic Range: This guideline mentions that products having a narrow therapeutic range designation in their label require specific drug substances that need pharmacodynamic effect monitoring alongside therapeutic drug concentration evaluation. The drug substances digoxin, lithium, phenytoin, theophylline and warfarin represent various BCS type recommendations. All firms must consult with their assigned review division to learn if their product meets the narrow therapeutic range requirements since pharmacodynamic and therapeutic drug concentration monitoring does not automatically classify a drug as part of that framework [21].

Materials Meant to be absorbable in the Oral Cavity: The BCS cannot justify waiving necessary in vivo BA/BE tests when delivering drugs through the mouth or via the buccal route or sublingual forms [21].

Conclusion

As shown through the provided examples a redefined BCS approach helps assess pharmaceutical substances for oral sus-

tained-release delivery by providing a simple method to identify which drug features are most likely to affect oral absorption. Reorganizing the dissolution number equation allows scientists to calculate the dissolving rate sensitivity across multiple particle sizes. The concept of solubility limited absorbable dose (SLAD) permits analysts that identify doses that can lead to intestinal solubility restricting oral absorption. When designing methods for optimum formulation and identifying prospective critical quality attributes (CQAs), it is also useful to see which aspects are most likely to compromise a drug's in vivo performance [22].
